Introduction

This paper provides a user guide to R-package MAMA. The package implements eight different methods that are designed to identify differentially expressed genes in meta-analysis of microarrays. A more comprehensive vignette can be downloaded from:

In here, we will demonstrate the features of the package with an example of meta-analysis in cancer microarray data, the comparison of expression profiles in MSI (microsatelite instable) and MSS (microsatelite stable) colon cancer. We gathered three microarray data from public databases. The data are stored in ColonData. It is an object of new S4 class - MetaArray, in which separate slots for gene expression data matrices (expression profiles), clinical sample characteristics and datanames were defined.

We start with package and sample data loading.

```

The original data sets have been preprocessed and subsampled in order to reduce the computational complexity of the meta-analysis. All data sets have been normalized and are in log_2 -scale. The corresponding sample sizes for the three datasets can be seen in outprint above. The same set of 500 gene has been selected in each dataset.

A different method is described in each of the parts below and the descriptions are independed from each other, so you can directly move to the method of your interest. A wrapper function for each method outperforms all necessary steps as one-line command.

We select the genes at significance level of 0.05 in all methods.

Methods that combine p-values

Introduction

In this part we will focus on methods that combine p-values [4], [5]. These methods are inspired by Fisher's S-statistic published in 1925 [6].

Two measurements of significance of change in gene expression are the most common. These are: value of test-statistic and p-value. In here, the p-values from study-specific analysis are combined into one p-value in sense of sum of logs. Methods differ in test statistic used to calculate the study-specific p-values.

Usage

Function metaMA is a wrapper function for this method. By

> pval<- metaMA(ColonData, "MSIstatus", which ="pval")

we combine study specific p-values(pval) in ColonData dataset using column "MSIstatus" from clinical data as class labels. pval is a list with seven slots. Study1 to Study3 are numeric vectors with indices of differentially expressed genes in data sets 1 to 3. AllIndStudies is a vector of indices of differentially expressed genes in at least one data set. Differentially expressed genes found by meta-analysis have their indices stored in Meta. A slot called TestStatistic is a vector with test statistics in meta-analysis. The last slot gene.names contains the names of the genes in the analysis.

Methods that combine effect sizes

Introduction

Methods that combine effect size use hierarchical model:

$$y_i = \theta_i + \epsilon_i, \epsilon_i \sim N(0, \sigma_i^2)$$

$$\theta_i = \mu + \delta_i, \delta_i \sim N(0, \tau_i^2),$$

where μ is true difference in mean expression between two classes, y_i denotes the measure effect for study i, with $i=1,..,k,\,\tau^2$ represents the between study variability, σ_i^2 denotes the within study variability. The analysis is different depending on whether a fixed-effect model (FEM) or a random-effect model (REM) is deemed appropriate. Under a FEM, $\tau=0$ is assumed, otherwise a REM need to be fit. The estimates of the overall effect μ are different depending on which model is used.

Two papers dealing with effect size combination as method for meta analysis of microarray have been published [4] and [9]. They differ in effect size definition and implementation.

Method presented in [4] offers three variants of effect sizes (classical and moderated T-test) and uses explicitly random-effect model. It is implemented as two functions EScombination for unpaired data and EScombination.paired for paired data.

On the other hand, in [9] the effect size is defined as Hedge's and Olkin's g and both random-effect and fixed-effect are available. Package GeneMeta [10] implements this method.

Algorithm

- 1. Data recoding.
- 2. Effect size calculation in each data set.
- 3. Decision between random-effect model (REM) and fixed-effect model (FEM).

- 4. Model application.
- 5. Identification of differentialy expressed genes.

Usage

Because there are two different ways of implementation of this method, we will discuss them separately.

Implementation from metaMA package

```
> es <- metaMA(ColonData, "MSIstatus", which = "ES")
```

```
DE IDD Loss IDR IRR
166.00 27.00 52.00 16.27 27.23
```

This object is a list with seven slots. Study1 to Study3 are indices of differentially expressed genes in data sets 1 to 3. AllIndStudies is a vector of indices of differentially expressed genes in at least one data set. Differentially expressed genes found by meta-analysis have their indices stored in Meta. A slot called TestStatistic is a vector with test statistics ("combined effect size") in meta-analysis. The last slot gene.names contains the names of the genes in the analysis (rownames of the gene expression data matrices).

Implementation from GeneMeta package

Function (ES.GeneMeta) wrapes data preparation and functions zScore, ScoresFDR.

```
> es2<-ES.GeneMeta(ColonData, "MSIstatus", nperm = 100)
```

nperm = 100 is used only for computational complexity. A thousand of permutation is more appropriate. We get a list with two slots. Columns of the first one (theScores) refer to:

- Effect_Ex_ are the unbiased estimates of the effect
- EffectVar_Ex_ are the estimated variances of the unbiased effects
- zSco_Ex_ are the unbiased estimates of the effects divided by their standard deviation
- Qvals are the Q statistics (my.Q) and df is the number of combined experiments minus one
- MUvals and MUsds are the overall mean effect sizes and their standard deviations
- zSco are the z scores
- Qpvalues is for each gene the probability that a chi-square distribution with df degree of freedom has a higher value than its Q statistic
- Chisq is the probability that a chi-square distribution with 1 degree of freedom has a higher value than zSco2

and the second one (*ScoresFDR*) is a list with three slots: pos,neg and two.sided. The first slot stores the results of the calculation, if the FDR is computed for the positive Z-scores, the second for the negative Z-scores and the last one for the two sided situation. Each slots contains a matrix with similar structure as theScores with additional FDR for each data set and combination.

Similarity of Ordered Gene Lists (SOGL)

Introduction

Similarity of Ordered Gene Lists is another method for meta-analysis of microarray. It is call as "comparison of comparisons" by its authors [?].

Briefly, it assigns a similarity score to a comparison of ranked (ordered) gene lists. The score is based on the number of overlapping genes in the top ranks. It computes the size of overlap for each rank. The final score is a weighted sum of these values, with more weight put on the top ranks.

Algorithm

- 1. Required data sets data sets with same set of genes are required.
- 2. Ranking of genes The genes are then ranked based on gene-wise test on difference of class mean. There is only one assumption about test result: a large positive test score corresponds to up-regulation and a large negative value to down-regulation.
- 3. Computing the overlap for each rank (from 1 to number of genes) we count the number of genes that appear in both ordered lists up to that position. It is denoted as $O_n(G_A, G_B)$, where G_A and G_B refer to ordered gene lists.
- 4. Similarity score First we compute a total overlap A_n at position n given as $O_n(G_A, G_B) + O_n(f(G_A), f(G_B))$, where f() means flipped list (down-regulated genes on top). Later we add weights to it and we sum it up to preliminary score. Weights $w_{\alpha} = e^{-\alpha \cdot n}$ are used as default and tunning of parameter α is needed. The weights are used to put more importance on top genes.

The algorithm above is valid for meta-analysis in which expression data are not available. However, in this situation we can not use same approach for tunning α .

Usage

Function performSOGL calculates the similarity score, its statistical significance and the genes responsible for the score.

```
> SOGL.res <- performSOGL(ColonData, varname = "MSIstatus",
+ test = "FCH", B = 100, which=c("score", "empirical"),
+ min.weight = 1e-05, two.sided = TRUE )</pre>
```

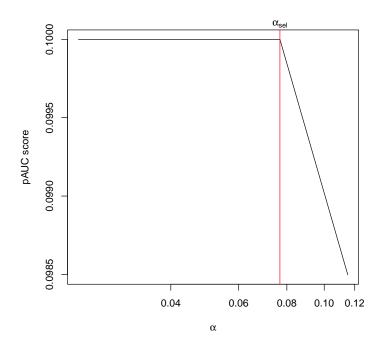

Processing data...Tuning alpha..Significance and genes...

SOGL.res is a list that contains:

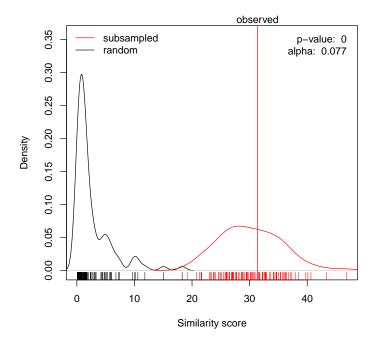

- ordering ordered gene lists as a data.frame where columns refer to datasets
- ullet alpha. selected selected value of alpha parameter
- alpha.considered vector of alpha considered for selection
- $\bullet~pAUC$ pAUC values related to all alphas considered
- random random scores (permutations of class labels)
- subsample scores after subsampling from each class and dataset
- emp.ci empirical confidence intervals for number of overlapping genes
- common.genes vector of number of overlapping genes
- \bullet score observed similarity score
- \bullet significance of the observed score in form of p-value
- genes genes that account for observed similarity score

The SOGL.res is an object of class SOGLresult for which plot function exist.

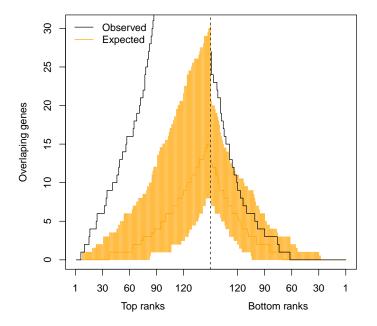

> plot(SOGL.res, "alpha selection")

> plot(SOGL.res, "density")

> plot(SOGL.res, "empirical CI")

The top graph shows pAUC of all α 's considered. The selected α is singed by red vertical line.

In the middle, one can see estimated densities of random (in black) and subsampled score (in red) for selected α . The observed similarity score is marked by vertical line. The bottom rugs are scores actually achieved in permutations. The bottom graph displays the empirical confidence intervals for number of overlapping genes to each position. Observed overlaps are drawn as black step-function.

RankProduct

Introduction

RankProduct is a non-parametric statistic that detects up-regulated and down-regulated genes under one condition against another condition. In our sample data set we look for difference in expression between MSI and MSS colon cancer.

It focuses on genes which are consistently highly ranked in a number of lists, for example genes that are regularly found among top up-regulated genes in many microarray studies. It assumes that under the null hypothesis the order of all items is random then the probability of finding a certain item among the top r of n items in a list is p = r/n. Rank product is defined by multiplying these probabilities $RP = \prod_i \frac{r_i}{n_i}$, where r_i is the rank of the item in the i-th list and n_i is the total number of the items on i-th list. The smaller the RP value the smaller the probability that the observation of the item at the top of the lists is due to chance. It is equivalent to calculating the geometric mean rank. A list of up- or down-regulated genes are selected based on the estimated percentage of false positive prediction (pfp) - known as false discovery rate (FDR), too.

Algorithm

Algorithm of the method has five steps:

- 1. Fold-change ratio is calculated in each data set.
- 2. Ranks are assigned (1 for the highest value) according to fold-change ratio. r_{gi} is rank of gene g in comparison i, where i is from 1 to K, where K is sum of products of number of slides in groups.
- 3. Rank Product for a gene (RP_g) is calculated as $\prod_i r_{gi}^{1/K}$
- 4. l permutations of expression values at each microarray slide is performed and all previous steps repeated. We obtain $RP_g^{(l)}$
- 5. Step 4 is repeated L times to estimate the distribution of $RP_g^{(l)}$. This distribution is used to calculate p-value and pfp for each gene.

Usage

Function RankProduct provides the tables of identified up- and down- regulated genes from a MetaArray-class object.

```
> rp <- RankProduct(ColonData, "MSIstatus", num.perm = 50,
+ gene.names = rownames(GEDM(ColonData)[[1]]) )

The data is from 3 different origins

Rank Product analysis for two-class case

Warning: Expected classlabels are 0 and 1. cl will thus be set to 0 and 1.

Starting 50 permutations...

Computing pfp...

Table1: Genes called significant under class1 < class2</pre>

Table2: Genes called significant under class1 > class2
```

Z-statistic - posterior mean differential expression

Introduction

The main idea of this method is that one can use data from one study to construct a prior distribution of differential expression and thus utilize the posterior mean differential expression, weighted by variances, whose distribution is standard normal distribution due to classic Bayesian probability calculation.

It is based on assumption that gene expression is normally distributed with mean μ_g and SD σ_g^2 and that we can estimate σ_g^2 by pooling together all genes with similar levels of mean intensity. The difference in gene expression is tested by

$$Z = \frac{D}{\sigma_D} = \frac{\overline{X}_1 - \overline{X}_2}{\sqrt{\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2}}} \sim N(0, 1),$$

where \overline{X}_1 and \overline{X}_2 denotes mean gene expression values in classes, σ_1^2 and σ_2^2 denotes the estimated SD in classes and n_1 and n_2 denotes the number of samples in classes.

Usage

Because the same number of samples in each class and study is used in primary publication of the method [16], we will first look at number of samples in our data.

                                  60.00
```

The smallest value in the tables above is 5, therefore we will randomly choose 5 samples in each class and data set. Function posterior.mean performs such data reduction and Z-statistic calculation. It has three required arguments: a data set as MetaArray object (data), name of clinical parameter with class labels (varname) and number of samples to be selected (nsamp).

Detecting differentially expressed genes

```
We apply this method by
```

```
> z.stat<-posterior.mean(ColonData, "MSIstatus", nsamp=5)
```

```
Pheno data is assumed to be in the first column of phenoData slot 0 marked as 0 1 marked as 1 Contrast will be 1 - 0
```

Results

```
> head(round(z.stat,3))
```

```
Zscore Pvalue
1552281_at 5.228 0.000
1552365_at -6.038 0.000
1552485_at -3.053 0.002
1552502_s_at -1.003 0.316
1552546_a_at 0.445 0.656
1552553_a_at -0.445 0.656
```

Only values of Z-statistic (Zscore) and their p-values (Pvalue) are the outputs from this method.

Notes and discussion

This implementation expects either same microarray platform or same scale of expression values (like after POE transformation [17]) in all data sets.

VennMapping

Introduction

VennMapping [20] is a method based on Venn diagrams and contingency tables. It looks for number of common genes in pairs of gene lists, statistical significance of observed match and returns also names of the common genes.

Algorithm

Algorithm of this method consists of three steps:

- 1. Calculation of fold-change in each data set.
- 2. Selection of significant (interesting) genes.
- 3. Comparison of gene lists pairs.

Usage

Function VennMapper selects genes in each dataset according to the fold-change cutoff and compares the lists of the selected genes.

```
> vm <- VennMapper(ColonData, varname="MSIstatus", cutoff=1)
> vm
```

MAP-Matches

Introduction

Meta-Analysis Pattern Matches (MAP-Matches) [21] is a method that extends VennMapping [20] and meta-profiling [22]. It is designed to analyze more distinct microarray data (search for common molecular mechanism in all types of cancer). It assumes same gene set in all data sets.

Algorithm

Algorithm of this method has five steps:

- 1. Calculation of T-statistic for each two classes in each data set.
- 2. Building matrix of T-statistics (T-matrix) with rows referring to genes and columns to pairs of classes and data set.
- 3. Selection of threshold for T-statistic.
- 4. Transformation of T-matrix into a binary matrix: 1 for T-statistics above threshold, 0 for T-statistics below threshold.
- 5. Statistical analysis of transformed T-matrix (more details in Usage section).

Usage

Function MAP.Matches provides all steps of MAP-Matches method in one-line command. In

```
> map <- MAP.Matches(ColonData, "MSIstatus", t.cutoff = "95.00%",
+ nperm = 100, sig.col = "p.col.strong")

Examining the data...
Statistical analysis...
Permutation:</pre>
```

100
Permuting class labels in dataset:
Denmark
Australia
Japan
Permutation:
50
100

the first argument is the dataset (MetaArray object), the second one is a column name of the class labels, nperm denotes the number of permutations and the last one sig.col is column name for selection of significant patterns - "p.col.strong" refer to the p-value of the strong matches when permutation of columns are used.

It returns a list of seven slots:

- *tests* is a vector of test statistics
- bin.matrix is a matrix of genes selected in each of the datasets
- *sumarization* is a sumarization of *bin.matrix*: the number of selected genes, the observed patterns and their empirical probabilities
- ullet MAP is data frame with the numbers of observed strong or soft matches for each gene pattern
- stat.analysis extends summarization with the p-values of the permutationbased tests of the statistical significance of the observed number of gene pattern matches
- *genes* is a list of gene names, where each slot refers to one gene pattern and contains the names of the genes for which the pattern was observed.
- all.genes is a vector of the names of the all genes in the analysis

METRADISC

Introduction

METRADISC [23] is unique among rank-based methods because it provides an estimate of heterogeneity as one of its outputs. Additionally the method can deal with genes which are being measured in only some of the studies. The implementation available in MAMA package is restricted to genes common in all microarray studies analyzed.

Algorithm

- 1. Gene Ranking In microarray analysis we usually test samples for a large number of genes. The results provide for each gene a test statistic and its statistical significance (p-value). Therefore we can rank the tested genes in each study based on direction in expression change and statistical significance. If there are n genes being tested, the highest rank n is given to the gene that shows the lowest p-value and it is up-regulated in diseased samples. Then follow all other up-regulated genes ranked according to increasing p-value. These are followed by down-regulated genes and the lowest rank (1) is given to gene that shows the lowest p-value and is down-regulated in diseased samples. Genes with equal p-values are assigned tied ranks.
- 2. The Average Rank and Heterogeneity metrics In this step we compute a average rank and heterogeneity metrics. The average rank R^* is defined as $R^* = \frac{\sum_{i=1}^s R_i}{s}$, where R_i is the rank of the gene in study i and s is total number of studies (i=1,2,...,s). The heterogeneity metrics Q^* is given by formula $Q^* = \sum_{i=1}^s (R_i R^*)^2$, it is actually generalization of Cochran's Q statistic.
- 3. Monte Carlo permutation test To obtain statistical significance for average rank and heterogeneity metrics we randomly permute the ranks of each study and the stimulated metrics are calculated. Then we repeat the procedure to generate null distribution for the metrics. Each variable is then tested against the corresponding null distribution. We are interested

genuinely in four statistical significances: for high average rank, for low average rank, for high heterogeneity and for low heterogeneity. Distinction between high and low average rank is important as we want to keep the direction of effect in mind. Ignoring it can lead to spurious results that a gene is consistently significant even if it is up-regulated in one study and down-regulated in second one. On the other hand, statistically low heterogeneity may suggest consistent results among different studies. The statistical significance for high average rank (R^*) is defined as the percentage of simulated metrics that exceed or are equal to the observed (R^*) . The statistical significance for low average rank (R^*) is defined as the percentage of simulated metrics that are below or equal to the observed (R^*) . Significance of heterogeneity is defined analogously.

Usage

Function METRADISC performs all steps of this method in one command.

```
> metra<-METRADISC(ColonData,</pre>
                              "MSIstatus", nperm = 1000)

```

It returns a list with ranks for each gene and dataset ranks, average rank and heterogeneity for each gene RQ and results of the Monte Carlo test MCtest.

Part I Results combination

In this part we are going to compare and combine outputs from all methods so we can look and changes in gene expression in various ways.

We are going to start with lists of differentially expressed genes, because this is the only one output common for all methods mentioned in this vignette. We will merge all lists into one variable via function join.DEG.

> lists<-join.DEG(pval, es, es2, SOGL.res, rp, z.stat, map, cutoff=0.05)
> names(lists)<-c("PvalCom", "ESCom","ESCom2","OrderedList","RankProduct", "Z-stat","MAP")
> summary(lists)

	Length	Class	Mode
PvalCom	212	-none-	character
ESCom	166	-none-	character
ESCom2	194	-none-	character
OrderedList	22	-none-	character
RankProduct	175	-none-	character
Z-stat	178	-none-	character
MAP	18	-none-	character

Now, we will transform this list to a binary matrix where rows refer to genes and columns to method and 1 means that the gene was identified as a differentially expressed gene in the method. Function make.matrix provides such transformation.

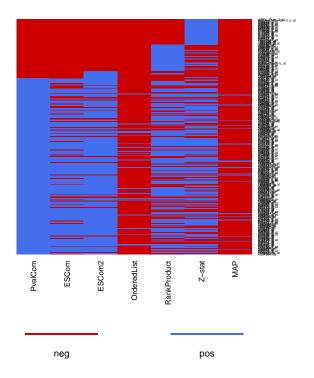

- > MAT<-make.matrix(lists)</pre>
- > MAT[1:5,1:5]

	PvalCom	${\tt ESCom}$	ESCom2	${\tt OrderedList}$	RankProduct
1554394_at	1	0	1	0	0
212662_at	1	1	1	0	0
1555370_a_at	1	0	0	0	1
240574_at	1	1	1	0	1
203553 s at	1	1	1	0	0

It is very popular to visualize results of microarray analysis as a heatmap. A heatmap is a graphical representation for a numeric matrix where values are presented as colors. Gene expression values are usually used in microarray analysis. In these pictures colors go continuously from green (for down-regulation) through black (for no change in gene expression) to red (for up-regulation). There are several R-packages which implement plotting heatmaps in slightly different way. Functions metaheat and metaheat2 are modification of two of them, so a discrete set of colors (only two in metaheat but even several in metaheat2) can be used with an appropriate legend.

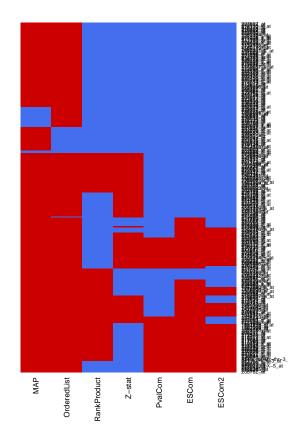

Function metaheat has three arguments: a data matrix (MAT), a number defining position of legend (legend=1 is legend drawn below the picture) and vector of colors (col).

> metaheat(MAT, legend=1, col=c("red3", "royalblue2"))

Function metaheat2 has as many arguments as heatmap.2 form gplots package and two more. Argument legend.names is a character vector with labels to be used in legend. Setting discret=TRUE will indicate that legend for discrete values should be drawn.

- > metaheat2(MAT, col=c("red3", "royalblue2"), legend.names=c("DEG",
- + "noDEG"), discrete=TRUE, trace="none",
- + dendrogram="none", cexCol=0.9)

The user can perform cluster analysis on MAT to search for similarities between methods or genes.

We can look at number of genes found by number of methods by

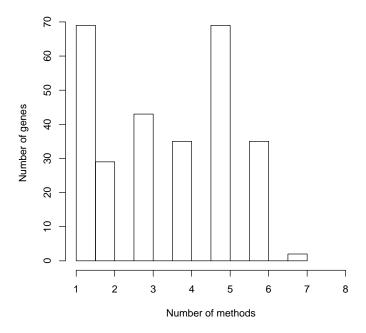

> dim(MAT)

[1] 282 7

According to the outsprint above, eight different methods have found 217 differentially expressed genes.

The histogram below shows that the most of the genes have been selected in only one method.

- > n.met<-apply(MAT,1,sum)</pre>
- > hist(n.met, main="", xlab="Number of methods",
- + ylab="Number of genes", xlim=c(1,8))

n.met is a numeric vector of number of methods that identified the gene as differentially expressed.

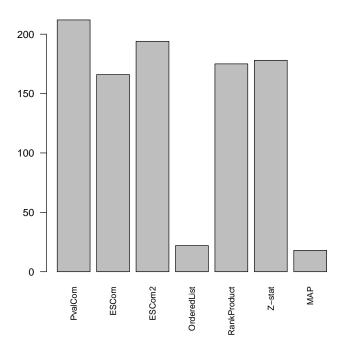

Next, we can look for example how many genes have been found as differentially expressed in at least 6 methods.

> dim(MAT[n.met>5,])

[1] 37 7

On the other hand, we can find out how many genes have been found by a method.

- > n.gen<-apply(MAT,2,sum)</pre>
- > barplot(n.gen, cex.names=0.8, las=2)

Function contig.tab provides a number of genes common in two gene lists. It can be applied to lists, too.

```
> TAB<-conting.tab(lists)
```

> TAB[1:5,1:5]

	PvalCom	ESCom	ESCom2	${\tt OrderedList}$	${\tt RankProduct}$
PvalCom	NA	166	186	22	141
ESCom	166	NA	166	22	125
ESCom2	186	166	NA	22	135
OrderedList	22	22	22	NA	22
RankProduct	141	125	135	22	NA

Expression of one gene

In this section we are going to focus on one gene and to look at its expression change from different points of view. The different points of view are represented by different approaches used in the methods.

First we will join all the available results to one list and then select only rows for one gene.

```
> results<-join.results(pval, es, es2, SOGL.res, rp, z.stat, map, metra)
> gene<-metagene("203008_x_at",results)</pre>
```

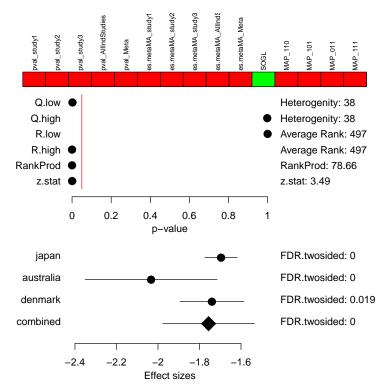

1 2 3 4 5 6 7 8

```
> names(gene) <- c("pval", "es.metaMA", "es.GeneMeta", "SOGL", "RP",
+ "z.stat", "MAP", "METRADISC")
> gene

This output provides much of the information available on the gene through all the described methods. It is a rather complicated structure, so we will try to represent it graphically in comprehensible form.

> plotgene(gene, datalabels=c("denmark", "australia", "japan", "combined"))

The picture above shows in top part occurrence of gene in lists of selected genes in some methods. The dark box means that the gene is present in the list. Values from objects: pvalt, ESt, x.z and probs are used in here.

The middle part is dedicated to p-values available in meta-analysis. Specific values of the statistics can be found on the right side of the chart. The vertical dashed line denotes the signifficance threshold 5%. P-values from MC, RankRes and z.stat are drawn in here.

Combination of effect size is plotted in the bottom graph. The point marks the effect size. Horizontal lines denote the variance of effect size. Statistical significance of the difference in gene expression (FDR adjusted) can be found on the right side of the chart. This graph uses values from the Scores and Scores FDR.
